Hypothesis: Liposomes made of single-chain amphiphiles and a large amount of sterols display several advantages including a limited permeability. In the present paper, we examine the possibility to prepare such non-phospholipid liposomes with interfacial polyethylene glycol (PEG) in order to improve their circulation in the blood stream. Cholesterol (Chol) was chosen as the PEG anchor.

Experiments: The phase behavior of mixtures of palmitic acid (PA) and cholesterol including various proportions of PEGylated cholesterol (PEG-Chol) was characterized. In conditions leading to the formation of fluid bilayers, properties of the resulting liposomes were assessed.

Findings: Up to 20 mol% of PEGylated cholesterol could be introduced without significant perturbations in fluid bilayers made of PA and cholesterol. With 10 mol% PEG-Chol, PA/Chol/PEG-Chol liposomes showed a very limited permeability to calcein and doxorubicin. Doxorubicin could be actively loaded in PA/Chol/PEG-Chol liposomes with a high drug loading efficiency and a high drug to lipid ratio. Pharmaco-kinetic experiments in rats indicated that interfacial PEG reduced the clearance of PA/Chol liposomes compared to the naked ones. However the lifetime of these non-phospholipid liposomes in the blood circulation was considerably shorter than that observed for control PEGylated phospholipid liposomes, a phenomenon associated with the negative interfacial charge of the PA/Chol/PEG-Chol liposomes.

1. Introduction

Liposomes are biocompatible, biodegradable, biologically inert, and weakly immunogenic, and they display several advantages for drug vectorization [1,2]. They can provide a slow release that expands the period during which the drug level remains in the therapeutic window, they can target, passively or actively, specific sites, and they can reduce the acute toxicity of drugs. One of the limitations of liposomes used as drug carriers for intravenous administration, however, is their rapid capture and removal from the blood circulation by the mononuclear phagocyte system (MPS), leading to their accumulation in the liver and the spleen. Because it leads to a tighter chain packing, the incorporation of cholesterol in liposomes reduces the transfer of lipids to high-density lipoproteins and prevents blood-protein binding, extending the liposome circulation lifetime in the blood stream [3–5]. A major breakthrough for improving circulation time and reducing MPS uptake was the introduction of gangliosides and sialic acid derivatives, such as monosialoganglioside (GM1) [6,7] at the water/liposome interface. A similar effect was observed with interfacial polyethylene glycol (PEG) [8–10]. This protective effect has been associated with the steric stabilization of liposomes that inhibits the uptake by MPS and prolongs the liposome circulation.
ligand [6,8,9,11]. The origin of this protection is still not fully understood but it has been proposed that the reduced binding of plasma proteins, including potential opsonizing factors, the limitation of direct interactions with cells of the reticuloendothelial system, and the inhibition of liposome–liposome aggregation could contribute to the reduced clearance of PEGylated liposomes [12–18].

PEG is an appealing macromolecule for obtaining sterically-stabilized liposomes as it displays biocompatibility, low toxicity, low immunogenicity and antigenicity, and good excretion kinetics [2]. Furthermore, its molecular weight can be easily modulated and it is relatively cheap to produce. It has been shown that PEG with a molecular weight between 1000, and 5000, anchored on bilayers with a phosphatidylethanolamine (PE) moiety displays a good miscibility with phospholipids; up to ~10 mol% PEG could be grafted without observing phase separation or micelle formation [13,19]. It was shown that improved circulation times of liposomes in the blood stream were obtained for liposomes with 2–10 mol% of interfacial PEG with a molecular weight between 350 and 2000 (anchored with distearoylphosphatidylethanolamine (DSPE) in these studies) [12,16]. The protection of liposomes against phagocytosis was also improved with introducing PEG with a molecular weight of 2000 at its interface [9]. An increase in the PEG molecular weight to 5000 had no effect on half-life time of liposomes in the blood stream or, in some reports, slightly decreased it [9].

The anchoring of PEG at the liposome interface is achieved by covalently attaching PEG to a phospholipid or a sterol. Because of the reactivity of the amine group, PEG-phosphatidylethanolamine (PEG-PE) is commonly used [2]. PEG-coupled with ceramide has also been synthesized as a neutral alternative [20]. Ishiwata and coll [21] used a sterol anchored PEG for modifying liposome surface. PEGylated cholesteryl ether led to an increased liposome circulation time in the blood stream similar to that previously obtained with PEG-DSPE [21–23]. PEG cholesteryl ester was also synthesized and incorporated in phospholipid liposomes and niosomes to achieve long circulation lifetime [23,24]. As a hydrophobic anchor for PEG, cholesterol is an alternative that presents distinct advantages. First, the chain ordering effects of cholesterol lead to less permeable bilayers. Second, it is neutral and this property provides a reduced binding of plasma proteins to liposomes. Third, cholesterol is chemically stable, a useful feature regarding storage.

It has been shown that it is possible to form non-phospholipid liposomes with single-chain amphiphiles and sterols – for a review, see [25,26]. The binary mixtures that could successfully form liposomes include negatively charged mixtures of unprotonated palmitic acid (PA) or its analogues with cholesterol (Chol) or some other sterols [27–29]. A distinct feature of these non-phospholipid liposomes is their high sterol content, which is between 50 and 70 mol%. This peculiar composition leads to a permeability that is drastically limited compared to traditional phospholipid liposomes. For example, it was found that about 70% of entrapped calcine, a negatively charged fluorophore, was still encapsulated after 1.5 years [28]. In addition, these liposomes are pH sensitive when they include a fatty acid or an alkylated primary amine as the single-chain amphiphile. The pH-triggered release could be fine-tuned by selecting a fatty acid with an appropriate pKₐ [28].

These non-phospholipid sterol-rich liposomes display an interesting potential as drug nanovectors. Their constituents are significantly more stable from a chemical point of view in aqueous suspension than phospholipids. Because of their very limited permeability, they could present a valuable alternative for drug encapsulation especially in the cases of challenging drugs that leak rapidly from conventional phospholipid liposomes such as 5-FU [30]. In these cases, it has been shown that it was difficult to retain the drug inside phospholipid-based liposomes, preventing the development of liposomal formulations for intravenous therapy displaying extended blood circulation lifetime and improved therapeutic activities. The restricted leakage observed for liposomes prepared with single-chain amphiphiles and sterols could therefore be advantageous in that context. In order to obtain a sustained drug release in parenteral delivery, nanovectors should also display a long circulation lifetime in the blood stream. Preliminary pharmacokinetic studies showed that, despite the very tight lipid chain packing that could limit protein adsorption, the sterol-rich PA/Chol liposomes were cleared very rapidly (less than 30 min) from the blood stream in rats (unpublished results). In the present study, we examined the possibility of introducing PEGylated cholesteryl (PEG-Chol) in non-phospholipid liposomes made of PA/Chol mixtures in order to combine the incomparably low permeability of those with improved blood circulation lifetime. We determined the impact of the incorporation of PEG-Chol on the stability of these unusual bilayers using deuterium and pulsed-field-gradient ¹H NMR, as well as cryo-transmission electron microscopy. We established the amount of PEG-Chol that could be included in the non-phospholipid bilayers without significant perturbation. We examined also the possibility to extrude the ternary mixtures to form large unilamellar vesicles (LUVs) and characterized the stability, the permeability and the pH sensitivity of the resulting liposomes. These findings provided us with a more detailed understanding of the influence of the hydration of the liposome interface on the stability of these self-assemblies. The present study also displays the feasibility of actively loading a drug in these non-phospholipid vesicles. Active loading is an advantageous way to obtain high drug loading efficiency and high drug to lipid ratios, two parameters presenting considerable benefit for therapeutic purposes and the pharmaceutical industries. Because these liposomes with high sterol content are very impermeable, active loading may present a specific challenge. We have therefore investigated whether LUVs prepared from PA/Chol/PEG-Chol mixtures could be actively loaded with doxorubicin (DOX), a broad-spectrum anticancer drug. Liposomal DOX has been shown to have improved therapeutic index and decreased toxicity [31,32]. It is somehow a benchmark regarding drug active loading. DOX is an amphipathic weak base that can be actively loaded into the aqueous compartment of phospholipid liposomes through ammonium sulfate gradient with a high drug loading efficiency. The ammonium sulfate gradient approach does not require the preparation of liposomes in acidic pH, nor to alkalinate theextraliposomal aqueous phase, in contrast to other chemical approaches used for active loading [33]. Finally, we conducted pharmacokinetic experiments in rats in order to determine the effect of interfacial PEG on the blood circulation lifetime and the biodistribution of PA/Chol/PEG-Chol liposomes. The pharmacokinetics was examined using DiD, a fluorescent lipophilic probe that labels the LUV walls and has, in general, limited transfer from labeled to unlabeled membranes [34].

2. Materials and methods

2.1. Materials

Hydroxypolyethyleneglycol cholesteryl ether, with PEG MW of 2000, (PEG-Chol) was purchased from NOF Corporation (Tokyo, Japan). Cholesterol (>99%), palmitic acid (99%), tris(hydroxymethyl)aminomethane (TRIS) (99%), 2-[N-morpholino]ethanesulfonic acid (MES) (99%), ethylenediaminetetraacetic acid (EDTA) (99%), NaCl (>99%), Triton X-100 (99%), and deuterium-depleted water (>99.99%) were supplied by Sigma Chemical Co. (St. Louis, MO, USA). Perdeuterated palmitic acid (PA-d₁₅) (98.9%) and deuterium oxide (>99%, D₂O) were from CDN Isotopes (Pointe-
Claire, QC, Canada). Calcein (high purity) and 1,1'-dioctadecyl-3,3',3'-tetramethylindodicarbocyanine perchlorate (DiD) were obtained from Invitrogen (Burlington, ON, Canada). Sephadex G-50 Medium was purchased from Pharmacia (Uppsala, Sweden). Methanol (spectrograde) and benzene (high purity) were obtained from A&C American Chemicals Ltd. (Montreal, QC, Canada), and BDH Inc. (Toronto, ON, Canada), respectively. DOX (hydrochloride from A&C American Chemicals Ltd. (Montreal, QC, Canada), and Methanol (spectrograde) and benzene (high purity) were obtained from Invitrogen (Burlington, ON, Canada). Sephadex G-50WX4 were supplied by Alfa Aesar (Ward Hill, USA). Dowex\textsuperscript{\textregistered} 50WX4 was obtained as a strong acidic cation exchange resin and converted to the sodium form. All solvents and products were used without further purification.

2.2. Multilamellar and large unilamellar vesicle preparation

Mixtures of PA/Chol/PEG-Chol were prepared by dissolving weighed amounts of the solid chemicals in a mixture of benzene/methanol 90/10 (v/v). The solution were then frozen in liquid nitrogen and lyophilized for at least 16 h to allow complete sublimation of the organic solvent. For the NMR experiments, PA was replaced by PA-d\textsubscript{5/6}. In order to form multilamellar vesicles (MLVs), the freeze-dried lipid mixtures were hydrated with a buffer. The final lipid concentration was 30 mg/ml unless otherwise stated. The suspensions were subjected to five cycles of freezing-and-thawing (from liquid nitrogen temperature to \(-70\) °C) and vortexed between successive cycles to ensure a good hydration of the samples. The MLVs were obtained by extruding MLVs using a handheld Liposofast extruder (Avestin, Ottawa, Canada). Typically the dispersions were passed 15 times through two stacked polycarbonate filters at room temperature.

2.3. \(^2\)H NMR spectroscopy

MLVs were prepared in a MES/TRIS buffer (TRIS 50 mM, MES 50 mM, NaCl 10 mM, EDTA 5 mM), providing a buffered range between pH 5 and 9. The MES/TRIS buffer was prepared with deuterium deuterated water for these experiments. The samples were then transferred into homemade Teflon holders. The \(^2\)H NMR spectra were recorded on a Bruker AV-600 spectrometer, using a Bruker static probe equipped with a 5 mm coil. A quadrupolar echo sequence was used with a 90° pulse of 2.9 µs and an interpulse delay of 35 µs. The recycling time was 60 s. In absence of a slow-relaxation component, namely a solid phase, the recycling delay was reduced to 0.3 s. Typically 4000 FIDs were co-added. The temperature was regulated using a Bruker VT-3000 controller. The proportion of the isotropic phase in the \(^2\)H NMR spectra showing the co-existence of a lamellar phase and an isotropic phase could be estimated from the difference in the spectrum areas prior to and after the elimination of the narrow central peak.

2.4. \(^1\)H NMR diffusion experiments

In order to assess the inclusion of PEG-Chol in the liposomes, the diffusion coefficient of PEG was determined on LUVs prepared from different compositions, using \(^1\)H pulsed-field-gradient NMR. These LUVs were obtained by extruding through two stacked polycarbonate filters (200 nm-pore size) an MLV suspension prepared in a D\textsubscript{2}O-based MES/TRIS buffer. \(^1\)H NMR diffusion experiments were performed on a Bruker AV-400 spectrometer operating at 400 MHz for \(^1\)H. The diffusion measurements were carried out at 25 °C using a Bruker diffusion probe (Diff60) equipped with a \(^1\)H/\(^2\)H 5-mm coil. This probe includes one gradient coil, along the z axis, capable of delivering magnetic field gradients up to 2900 G/cm. The gradient strength was calibrated from the diffusion coefficient of 1% H\textsubscript{2}O in a D\textsubscript{2}O sample. The diffusion coefficients were measured using the stimulated echo pulse sequence [35]. Trapezoidal gradient pulses (\(\delta\)) of 1.50 ms and inter-pulse delays (\(\Delta\)) of 100 ms were applied. Typically, 32 scans were co-added for a given gradient strength and 32 gradient magnitudes were used for each attenuation curve. The sample temperature was controlled using the gradient coil cooling unit and was calibrated using ethylene glycol. The diffusion coefficients were obtained by fitting the variation of the echo intensity as a function of the gradient strength (G) using the following equation:

\[
\ln(S/S_0) = -(G/\delta)^2 D (\Delta - \delta/3)
\]

where S and S\textsubscript{0} are the integrated echo intensities with and without a field gradient and γ the gyromagnetic ratio of protons. All the curves could be well fitted with this single-diffusion-coefficient model.

2.5. LUVs characterization

The hydrodynamic diameters of the LUVs were measured at 25 °C by dynamic light scattering (DLS) using a Malvern nanosizer. The curve fittings of correlation functions were performed using an exponential fit (CONTIN approach) for size (hydrodynamic diameter) determination. The scattering light intensity was adjusted by diluting the dispersions with the MES/TRIS buffer.

The conditions for the cryogenic transmission electron microscopy (Cryo-TEM) technique are detailed elsewhere [36]. Briefly, an aliquot of a LUV sample (~1 µL) was deposited on a copper grid covered with a carbon-reinforced holey polymer film, dabbed with a filter paper to form a thin film (10–500 nm). These steps of the sample preparation were performed within a custom-built climate chamber at 25 °C and >99% relative humidity. The grid was then plunged into liquid ethane held at a temperature just above its freezing point (\(-183\) °C). The vitrified sample was kept below –165 °C and protected from ambient conditions during the transfer from the preparation chamber to the microscope as well as during the data acquisition. The micrographs were obtained using a Zeiss EM 902A Transmission Electron Microscope (Carl Zeiss NTS, Oberkochen, Germany), in the zero loss bright-field mode, with an accelerating voltage of 80 kV. The digital images were recorded under a low dose conditions with a BioVision Pro-SM slow scan CCD camera (Proscan GmbH, Scheuring, Germany). Their contrast was enhanced using an underfocus of 1–2 µm.

2.6. Permeability measurements

The permeability of the LUVs was measured using a standard procedure based on the self-quenching property of calcein at high concentration [28,37]. Briefly, LUVs loaded with the fluorophore were prepared from PA/Chol/PEG-Chol mixtures hydrated with a MES/TRIS buffer, pH 8.4, containing 80 mM of calcein; the resulting MLV suspension was extruded, using filters with 100 nm-pore diameter. The calcein-containing LUVs were separated from free calcein by gel permeation chromatography, using Sephadex G-50 Medium gel (column diameter: 1.5 cm, length: 25 cm), equilibrated with an iso-osmotic MES/TRIS buffer (MES 50 mM, TRIS 50 mM, NaCl 130 mM, EDTA 5 mM, pH 8.4). The collected vesicle fraction was diluted 100 times with buffers having different pH to obtain a final fatty acid concentration of about 20 µM. This dilution step was set as time = 0. These stock LUV suspensions were then incubated at room temperature.

To study the passive leakage (external and internal pH of 8.4), the calcein fluorescence intensity was measured from an aliquot of the stock LUV suspension freshly isolated by gel permeation chromatography, prior (\(t_i\)) and after (\(t_i+\tau\)) the addition of Triton

X-100 (10 µL of a 10 (v/v)% solution prepared in the MES/TRIS buffer). The low fluorescence intensity measured prior to the detergent addition was associated with calcein that was initially completely encapsulated whereas the fluorescence intensity measured after addition of Triton X-100 corresponded to the complete release of entrapped calcein.

After a given incubation time, the calcein fluorescence intensity was measured on another aliquot of the same stock LUV suspension before (\(I_i\)) and after (\(I_{i+T}\)) the addition of Triton X-100. The percentage of encapsulated calcein at that time in the LUVs was calculated according to:

\[
\%\text{of encapsulated calcein} = \left( \frac{I_{i+T} - I_i}{I_{i+T}} \right) \times 100
\]

The percentage of release corresponded to (100-% of encapsulated calcein).

The pH-triggered leakage of calcein was also examined. The percentage of released calcein was calculated using Eq. (2): \(I_i\) and \(I_{i+T}\) were measured at pH 8.4, the initial pH, before and after the addition of Triton X-100 respectively, whereas \(I_i\) and \(I_{i+T}\) were obtained on an aliquot at a modified pH, before and after the addition of Triton X-100 respectively. The pH effect was examined for an increase as well as a decrease in pH. Calcein fluorescence intensity was relatively constant over the investigated pH range [37].

The fluorescence intensities were recorded using a Photon Technology International spectrofluorometer. The excitation and emission wavelengths were 490 and 513 nm respectively and the band path widths were set to 1.0 and 1.6 nm for the excitation and emission monochromators, respectively.

2.7. DOX active loading experiments

Active loading of doxorubicin was carried out using an ammonium sulfate gradient [33]. PA/Chol/PEG-Chol solid mixtures were hydrated with an ammonium sulfate solution (120 mM). The PA/Chol/PEG-Chol LUVs (extruded using filters with 100-nm diameter pores) were prepared as described above. The ammonium sulfate gradient was created by gel permeation chromatography, using Sephadex G-50 Medium gel (column diameter: 1.5 cm, length: 25 cm), equilibrated with an iso-osmotic NaCl solution (150 mM). An aliquot of a DOX solution (5 mM, prepared in water containing 150 mM NaCl) was added to the collected vesicles (~3 mg of lipids/mL) in order to have a DOX/lipid molar ratio of 1/15. The LUV suspensions were incubated at ~70 °C for 24 h. In order to determine the drug loading efficiency, the LUV suspensions incubated with DOX were diluted 100-folds with the NaCl solution. Converted Dowex® 50WX4 resin was added to an aliquot to remove the free DOX by complexation. The sample was centrifuged at 4000 rpm for 3 min and DOX absorbance at 480 nm was measured. The absorbance was also measured for an aliquot without resin to obtain the total amount of DOX. The release of liposome-entrapped DOX was also characterized by UV–vis spectroscopy using the resin treatment to eliminate the released drug. HPLC-MS analysis was carried out on LUV aliquots treated with the resin in order to quantify the drug to lipid ratio.

2.8. Pharmacokinetics and biodistribution

Sprague–Dawley rats (300–350 g) (Charles River, L’Arbresle, France) were housed and maintained at the University animal facility (SCAHU). All the animal experiments were performed in agreement with the EEC guidelines, and the “Principles of Laboratory Animal Care” (NIH Publication No. 85-23, revised 1985), and with the agreement of Comité d’éthique pour l’expérimentation animale des Pays-de-la-Loire (authorization CEEA; 2012–180). Rats (\(n = 8\) for each group) were anesthetized (with isoflurane). PA/Chol, PA/Chol/PEG-Chol or DSPC/Chol/PEG–DSPE LUVs in phosphate buffer (137 mM NaCl, 2.7 mM KCl, 10 mM Na2HPO4, 1.76 mM KH2PO4, pH 7.4), were prepared as described above; the final lipid concentration was 7 mg of lipids/mL. DiD, used to label the LUV walls, was added to the organic lipid solution, before the freeze-drying step, to obtain a final DiD/lipid ratio of 2 (w/w%). The LUV size and zeta potential were not affected by the presence of DiD, confirming that the fluorophore, at that concentration, did not affect the assembly [34]. A LUV aliquot of 400 µL was intravenously delivered (caudal veins) to each rat. At various time points, from 5 min to 24 h following the injection, blood samples (about 400 µL) were collected. The rats were sacrificed at the last time point, and liver, spleen, heart, lungs, brain, and kidneys were harvested.

Calibration curves were obtained by mixing liposomes with fresh blood at various concentrations and by measuring the fluorescence using a microplate reader Fluoroscan Ascent® (Labsystems SA, Cergy-Pontoise, France). Excitation and emission wavelengths were fixed at 646 and 678 nm, respectively. The liposome concentrations in blood at the various time points were calculated on the assumption that blood represents 7.5% of rat body weight [38]. Organ fluorescence imaging and analysis were performed using a fluorescence imaging system (CRI Maestro™, Woburn, MA, USA). The photon average count between 630 and 600 nm was obtained from each organ, using a time exposition of 500 ms. The reported values correspond to the mean values ± standard deviations obtained for \(n = 8\). The statistical differences were established using the Mann Whitney test.

3. Results

3.1. NMR Results

Fig. 1 presents \(^{2}H\) NMR spectra of PA-d_{31}/Chol/PEG-Chol mixtures of various compositions: the PA-d_{31}/sterol molar ratio was always 30/70 and cholesterol was progressively substituted by PEG-Chol. This set of data provided us with the proportion of PEG-Chol that could be incorporated in the mixture while keeping a fluid lamellar arrangement. The spectra of PA-d_{31}/Chol (30/70) mixture, pH 8.4 (Fig. 1A, top row), were essentially characteristic of a fluid lamellar phase. They corresponded to several overlapping powder patterns with different quadrupolar splittings, associated with the gradient of orientational order existing along the acyl chains [39,40]. The quadrupolar splitting of the outermost doublet of the spectrum recorded at 25 °C was 55 kHz; this large value is typical of lipids in the lamellar liquid ordered (lo) phase [39,40]. These spectra indicated that the lo phase formed by this mixture was stable over the whole investigated temperature range, in agreement with previous results [39]. Actually, temperature variations between 25 and 60 °C had limited effect on these systems, the value of the quadrupolar splitting of the outermost doublet decreasing by only ~5 kHz. Once 20% or more of PEG-Chol was introduced in the liposomes, a narrow peak centered at 0 appeared, indicating the formation of an isotropic phase.

The evolution of the proportion of isotropic phase in the ternary systems, as a function of PEG–Chol content is summarized in Fig. 2. For PEG–Chol content lower than or equal to 20%, all the fatty acid appeared to exist in the fluid lamellar phase. Larger proportions of PEG-Chol led to the formation of an isotropic phase that coexisted with the lo lamellar phase. The proportion of the isotropic phase steadily increased with the proportion of PEG-Chol. More than 85% of PA-d_{31} existed in the isotropic phase for a PA-d_{31}/Chol/PEG-Chol 30/20/50 mixture. Higher temperatures favored the formation of the isotropic phase in the mixtures that included 30% or more of PEG-Chol (Fig. 1A).
It has been shown that a decrease in pH favors the formation of solid components in the PA/Chol system [27,41], a property giving rise to pH-sensitive formulations. In order to investigate the pH sensitivity of the PEG-containing mixtures, their spectra were recorded at pH 5.0 (Fig. 1B). At temperatures below 50 °C, the spectra of a PA-d31/Chol 30/70 mixture displayed only a signal typical of solid and immobile PA-d31. At 50 °C and above, the solid signal completely disappeared and only a fluid lamellar component was observed, in agreement with previously reports [27,41]. The widths of these spectra were found to be very similar to those observed at pH 8.4 (Fig. 1A), suggesting a comparable orientational order of the alkyl chain. The presence of PEG-Chol in the mixtures modified the phase behavior of the mixture and led to the formation of fluid bilayers at low temperatures (below 50 °C). For example, at 25 °C, the spectrum of PA-d31/Chol (30/70) mixture indicated that the fatty acid was completely solid whereas it was completely in a fluid lamellar phase in the PA-d31/Chol/PEG-Chol 30/63/07 mixture. The co-existence of solid and fluid bilayers was observed for the mixtures containing 4% of PEG-Chol. The presence of PEG-Chol in the mixture downshifted the solid-to-fluid lamellar phase transition as the system containing 4% PEG-Chol was completely fluid at 37 °C and that with 7% PEG-Chol existed in the fluid lamellar phase over the whole investigated temperature range. At high temperatures and pH 8.4, the presence of PEG-Chol has a limited effect on the structure of PA-d31/Chol/PEG-Chol self-assemblies. The measured quadrupolar splittings were considerably large and similar to those obtained for the mixture without PEG-Chol in the same conditions; these 2H NMR
spectra indicated the formation of fluid lo bilayers. By promoting the formation of these fluid bilayers at low temperatures, PEG-Chol inhibited the pH sensitivity of the PA/Chol mixture; stable fluid bilayers were observed between pH 5.0 and 8.4 when the system included between 7% and 20% of PEG-Chol.

The $^2$H NMR spectra provided a detailed characterization of the phase behavior from the fatty acid (PA-$d_{31}$) point of view. In order to examine the behavior of PEG-Chol in these systems, we measured the diffusion of PEG using pulsed-field-gradient $^1$H NMR. This analysis is based on the assumption that it is possible to distinguish on the basis of the PEG diffusion coefficient between PEG-Chol inserted in 200-nm liposomes and PEG-Chol that would exist under a micellar form. Typically, there is one order of magnitude difference in the diffusion coefficient of micelles ($\sim 10^{-11}$ m$^2$/s) and of liposomes ($\sim 10^{-12}$ m$^2$/s) [42]. The diffusion coefficient was obtained from the PEG-Chol band at $\sim 3.66$ ppm. For all the investigated PA-$d_{31}$/Chol/PEG-Chol mixtures (PEG-Chol proportions varying from 0 to 100), a single exponential could reproduce well the decay of the relative signal as a function of the gradient strength (see Eq. (1)) and, consequently, a single diffusion coefficient was inferred (Fig. 3). Pure PEG-Chol in D$_2$O forms micelles [21,43]. The measured diffusion coefficient in these conditions was $2.0 \times 10^{-11}$ m$^2$/s, a value corresponding to that reported for PEG2000-PE micelles [42]. When PEG-Chol proportion in a mix with PA and cholesterol was between 1% and 20%, PEG diffusion coefficients were relatively constant and corresponded to about $2.4 \times 10^{-12}$ m$^2$/s. This value was consistent with the diffusion coefficients reported for PEG2000-PE inserted in 100-nm phospholipid liposomes ($\sim 5 \times 10^{-12}$ m$^2$/s) [42]. When the proportion of PEG-Chol was increased, the PEG diffusion coefficient also increased to reach, in the case of PA-$d_{31}$/Chol/PEG-Chol 30/20/50 mixture, a value similar to that of pure PEG-Chol micelles in D$_2$O. These results showed that the presence of up to 20% of PEG-Chol in fluid bilayers made of PA and cholesterol had no significant influence on its diffusion coefficient. When its proportion was higher, the formation of smaller self-assemblies that diffused faster than liposomes was reported. This conclusion is in good agreement with the $^2$H NMR results indicating the fast isotropic motions of PA-$d_{31}$ in mixtures where the proportion of PEG-Chol was higher than 20%.

3.2. Dynamic light scattering and Cryo-TEM

It has been shown that, despite their very high cholesterol content, it is possible to extrude several mixtures of sterols and single-chain amphiphiles when they form a lo phase [27,29,44,45]. We examined the influence of PEG-Chol on the extrusion process of PA/Chol/PEG-Chol ternary systems. LUVs could be formed by extrusion of PA/Chol/PEG-Chol fluid bilayers with 30/60/40 and 30/60/10 M ratios, between pH 5.5 and 9.5. Typically a unimodal size distribution with an average diameter of about 100 nm, consistent with the pore diameter of the polycarbonate filters (100 nm), was obtained. For example, the extrusion of PA/Chol/PEG-Chol (30/60/10) suspension at pH 7.4, led to LUVs with an average diameter of 108 ± 3 nm, and a polydispersity index of 0.10 ± 0.03. PA/Chol/PEG-Chol LUVs were also examined by cryo-TEM (Fig. 4). The impact of pH was studied by varying the external and internal pH to 8.4 or 5.0. The mixture containing 4% PEG-Chol, with internal/external pH 8.4/8.4 led predominantly to spherical vesicles of fairly uniform size. When both inside and outside pH of LUVs were 5.0, LUVs (Fig. 4b) were also obtained but it seemed that they were less spherical than those formed at pH 8.4. The morphology of the vesicles prepared in the presence of 10 mol% PEG-Chol were affected; although spherical and unilamellar vesicles dominated the samples, elongated, peanut-like, and convex (red blood cell like) shaped vesicles were observed for both pH 8.4/8.4 and 5.0/5.0.

3.3. PA/Chol/PEG-Chol LUV permeability

The PA/Chol/PEG-Chol LUVs loaded with calcein were prepared by extrusion at pH 8.4 as described above. The entrapped calcein showed an initial self-quenching of more than 0.90, a value expected for an 80-mM calcein solution [37]. The passive release of calcein from these vesicles at pH 8.4 was determined as a function of time (Fig. 5). The leakage from PA/Chol/PEG-Chol LUVs (with a molar composition of 30/66/04 and 30/60/10) was very limited; even after three months, no significant release could be detected. This notable ability to retain the encapsulated calcein compares advantageously to other PEGylated liposomes [46,47] for example.

The permeability of the PA/Chol/PEG-Chol LUVs was also assessed as a function of pH (Fig. 6). As shown previously [29], PA/Chol LUVs (30/70 M ratio) are pH-sensitive: they were stable between pH 7 and 9.5 whereas a significant calcein release was observed for pH 6.0 or below. Contrasting with this behavior, no significant calcein release was observed from the LUVs containing PEGylated cholesterol when the external pH was modified between 5.5 and 9.5. These results indicate that the presence of PEG-Chol in the LUVs impedes their pH sensitivity.
3.4. DOX active loading and release

The effectiveness of active loading using a transmembrane ammonium gradient was assessed for liposomes made of PA/Chol/PEG-Chol (30/60/10 M ratio). The encapsulation efficiency of DOX was estimated to 84%, and the resulting drug to lipid ratio was 0.06 (molar ratio). These parameters are comparable to those previously obtained with phospholipid-based liposomes [48–50]. It should be pointed out that the reported trapping efficiency was very good since the drug to lipid ratio is expressed in molar terms.

Fig. 4. Cryo-micrographs of extruded PA/Chol/PEG-Chol LUVs in a molar ratio of 30/66/04 (a) pH 8.4/8.4 inside/outside, (b) pH 5.0/5.0, and in a molar ratio of 30/60/10 (c) pH 8.4/8.4, (d) pH 5.0/5.0. The scale bar corresponds to 200 nm.

Fig. 5. Passive leakage of entrapped calcein from LUVs prepared with mixtures of PA/Chol/PEG-Chol (□) 30/66/04, and (△) 30/60/10 (molar ratio); the leakage was measured at room temperature, pH 8.4.

Fig. 6. Effect of the external pH on the calcein release from (■) PA/Chol/PEG-Chol 30/70/00, (△) 30/66/04, and (▲) 30/60/10 LUVs. The measurements were carried out at room temperature, ~24 h after the pH change.
and the investigated liposomes were formed from a single-chain amphiphile, in contrast to phospholipids, which bear two hydrophobic chains. The stability and the passive release of DOX-loaded liposomes were also examined. The results are summarized in Fig. 7. It is shown that the non-phospholipid liposomes displayed a very limited permeability to DOX; the drug slowly leaked out from the LUVs and only ~20% of encapsulated DOX was released after a three-month period. The stability of DOX-loaded PA/Chol/PEG-Chol LUVs was significantly improved compared to active-loaded phosphatidylcholine liposome containing 38 mol% of cholesterol and 5 mol% of PEG-lipid (PEG-DSPE or PEG-Chol). For those formulations, more than 30% of the encapsulated DOX was released within three days, in similar conditions [23].

3.5. Pharmaco-kinetics

The circulation times of naked and PEGylated PA/Chol LUVs, as well as of DSPC/Chol/PEG-PE LUVs as a control, have been determined in rat blood system. The DiD fluorescence measurements (Fig. 8) show that naked PA/Chol (30/70) LUVs were cleared very rapidly from the blood stream. After 0.16 ± 0.05 h, half the dose was still in the blood circulation. PA/Chol/PEG-Chol (30/60/10) LUVs displayed a significantly improved circulation time by a factor of ~7: half the dose was present in the blood circulation after the injection 1.09 ± 0.23 h. Despite this enhancement, the LUV clearance was much faster than that observed for the control phospholipid cholesterol-containing PEGylated LUVs. For the DSPC/Chol/PEG-PE LUVs (55/45/5), 50% of the dose was cleared after 17.5 ± 2.0 h, and ~25% of the injected dose remained in the blood after 24 h, a result consistent with previous studies [51]. The biodistribution after 24 h was determined for naked and PEGylated PA/Chol LUVs (Fig. 9) (the DSPC/Chol/PEG-PE LUVs remaining in the blood stream after 24 h would have interfered with the measurements, increasing the apparent distribution in the highly vascularized organs). As expected, most of DiD was found in the liver for both formulations, indicative of the MPS uptake [51]. A significant quantity was also found in the spleen for PA/Chol LUVs. It appears that the presence of PEG at the interface has affected the biodistribution as, in addition to liver, a significant amount of DiD was also found in the lungs and the heart whereas less dye was found in the spleen, a phenomenon previously observed upon PEGylation of liposomes [9].

4. Discussion

The present study reveals that it is possible to introduce PEGylated cholesterol into liposomes prepared from palmitic acid and cholesterol. At least 10 mol% of PEG-Chol can be included in the ternary system before non-liposomal structures start to appear. 2H NMR results show that all the palmitic acid molecules are included in the fluid lamellar phase while the diffusion coefficient of PEG-Chol indicates that PEG-Chol molecules are anchored to the liposomes. Moreover the cryo-EM analysis showed that spherical unilamellar vesicles dominated the samples for the PA/Chol mixtures that included 4 and 10 mol% of PEG-Chol. With 10 mol% PEG-Chol, different morphologies such as elongated, dumbbell-like and erythrocyte-like shapes were observed occasionally. As discussed elsewhere [43,52], the occurrence of these shapes could be associated with a partial component segregation in the vesicles leading to a cholesterol content somewhat lower in the highly curved “ends” of the vesicles while PEG-Chol is enriched in these regions, reducing the interPEG steric repulsion. Beyond 20 mol% of PEG-Chol, an isotropic phase is formed (Fig. 2, looking at PA-d31) and the diffusion coefficient of PEG-Chol increases to a value similar to that obtained for PEG-Chol micelles (Fig. 3). It has been shown that an increasing proportion of PEG-lipid in bilayers of several systems leads to a progressive transformation of liposomes.
There is initially the formation of open-bilayer fragments and disks that decrease in size with higher concentration of PEG-lipids to become indistinguishable from PEG-lipid micelles [52,53]. Therefore, the evolution of the NMR signals is likely due to the formation of mixed micelles of PEG-Chol with PA, and cholesterol. On the basis of the PFG NMR measurements, it appears that the bilayer solubilization is complete and only micellar-like forms are obtained when the mixture contains about 50% of PEG-Chol. The observation of disks and bilayers fragments has been reported upon the inclusion of PEG-lipid in phospholipid bilayers. As discussed in detail elsewhere [43,52,54,55], this morphology transition was observed for a PEG-lipid content varying between 7 and 20 mol%, depending on several parameters including the molecular weight of PEG, and the composition of the bilayers. Because the NMR data and the cryo-TEM images confirmed that 10 mol% of PEG-Chol can be inserted in PA/Chol liposomes without significant morphological changes, we have focused our characterization of permeability and of pharmaco-kinetics on liposomes formed by PA/Chol/PEG-Chol mixtures with a PEG-Chol content of 10 mol% or less.

It has been shown that PA/Chol system forms stable fluid bilayers only at high pH (>7.5) while lower pH favors the formation of solid phase cholesterol and palmitic acid [41]. The protonation state of the carboxylic group dictates the bilayer stability through its modulation of the lipid mixing properties and the bilayer interface hydration. At lower pH, PA head group is protonated, favoring phase separation from cholesterol and reducing the hydration of the bilayer interface; as a consequence, the destabilization of the fluid lamellar phase is observed [28,45]. In the present work, it is shown that the incorporation of PEG-Chol favors the formation of a lo phase at lower pH. For example, typical spectrum of cholesterol inserted in fluid bilayers was obtained at pH 5, 25°C, when the PA-d31/Chol system included 7 mol% PEG-Chol (Fig. 1B). It has been proposed that interfacial PEG may hinder the protonation of carboxylic groups located at the interface [56]. Consequently, a larger proportion of PA may be unprotonated in PEGylated liposomes, favoring lamellar phases, and, as a consequence, a reduced pH-sensitivity. It is also possible that the PEGylation of cholesterol leads to steric repulsion of the modified cholesterol molecules in the plane of the bilayer, thus promoting mixing and formation of a homogenous lo phase. The presence of PEG hydrophilic chains at the bilayer interface maintaining a suitable degree of hydration of the bilayer, and the strong positive spontaneous curvature of PEG-lipids may also play a role in the hindrance of the pH-induced phase transition. The promotion of a fluid bilayer phase by PEG-Chol makes possible the extrusion of the ternary mixtures to form SUVs, even at low pH such as 5.0; this operation was proved impossible for PA/Chol system at such low pH [45].

PEG-Chol-containing non-phospholipid liposomes display a limited permeability compared to that generally observed for PEGylated phospholipid liposomes, as is shown in this paper for calcine as well as for DOX. This distinct impermeability is consistent with that previously reported for other similar systems prepared from a single-chain amphiphile and a sterol [27,29]. This property has been associated with the high content of cholesterol leading to an increase in acyl chain order [40,57] and a decreased permeability. The insertion of PEGylated cholesterol in the PA/Chol bilayers does not appear to have a significant effect on the passive permeability of the resulting SUVs. This observation is in good agreement with the absence of influence of PEG-Chol on the quadrupolar splittings of PA-d31 in the 2H NMR spectra of PA-d31/Chol/PEG-Chol systems, the splittings being representative of the alkyl chain orientational order.

It was shown that the content release from PA/Chol liposomes could be triggered by a pH variation; [28,29] pH < 7 would lead to the formation of solid PA as well as solid cholesterol, causing the complete disruption of the liposomes and as a consequence, the complete release of their content. This pH-stimulated release is however significantly reduced for the PEG-coated non-phospholipid liposomes. Actually, practically no release can be triggered by decreasing the external pH to 5.5, in contrast to a pH-triggered release of about 20% for the naked PA/Chol liposomes (Fig. 6). This result is consistent with the impact of interfacial PEG on the phase behavior of PA/Chol mixtures. As discussed above, the presence of interfacial PEG promotes the formation of a fluid lamellar phase at pH as low as 5. As a consequence, the solid–fluid transition observed for the PA/Chol system during a pH variation from 5 to 8.4 is no longer detected in the presence of 10 mol% PEG; the system remains in the fluid lamellar phase over the whole pH range and, as a consequence, their liposomes remain stable and impermeable. The decrease in pH sensitivity appears to be commonly observed for PEG-coated phospholipid liposomes. For example, the inclusion of 1–5 mol% PEG-DSPE in pH-sensitive DOPE/oleic acid liposomes shifted the pH-triggered release curve toward more acidic regions and reduced the extent of the leakage that could be induced [56]. The presence of only 1 mol% PEG-DSPE in the formulation led to a decrease in release from >90% without PEG to ~20%, when the pH was set to 5. Similarly the pH-sensitivity of cholesterol hemisuccinate/DOPE liposomes was attenuated in the presence of PEG-PE: [58] the nearly complete release of the liposome content could be triggered at pH 5, while the inclusion of 2 mol% PEG-PE reduced the pH-induced leakage to ~20%. Therefore, the presence of interfacial PEG changes the chemistry of the bilayer/aqueous milieu interface and attenuates the pH-response of functional groups such as the carboxylic group, leading to the reduction or even the loss of pH-responsiveness of PEGylated liposomes.

We also determined the performance of PA/Chol/PEG-Chol liposomes for active loading of DOX. It is shown that DOX could be successfully loaded in the aqueous compartment of these SUVs with a conventional approach based on an ammonium sulfate gradient. A high drug loading efficiency (84%) and a high drug to lipid ratio (0.06) were obtained, despite the much reduced bilayer permeability of these liposomes and the presence of interfacial PEG. The reported values are comparable to those reported for phospholipid liposomes [33].

Finally, the pharmaco-kinetic results indicate that PA/Chol/PEG-Chol SUVs injected intravenously display an extended circulation time in the blood stream compared to naked ones but they are cleared more rapidly than DSPC/Chol/PEG-PE liposomes. The circulation lifetime depends on several parameters [10,11] and its predictability is, with our current knowledge, limited. The presence of interfacial PEG increases the circulation time of PA/Chol SUVs as expected; the PEGylated SUVs remain in the blood stream considerably longer than the naked ones (a half-life time that is 6 times longer). In addition, a reduced amount of dye was found in the spleen when SUVs were PEGylated, another indication of a limited uptake by the MRS. A tight chain packing in the hydrophobic core bilayers has been shown to extend the circulation time of liposomes, among other, by inhibiting the binding of plasma proteins [5,10]. "H NMR results indicate that the orientational order of PA acyl chain is very high, likely because of the large cholesterol content. The combined features of interfacial PEG and highly ordered bilayer core are predictive promoters of extended circulation time in the blood. However, several negatively charged lipids were shown to markedly shorten the liposome clearance kinetics [10,59]. This phenomenon was associated with a higher binding affinity of these anionic liposomes for blood proteins. It appears that this unfavorable electrostatic factor dominates the others in determining the lifetime of PA/Chol/PEG-Chol liposomes in the blood circulation and leads to a relatively rapid clearance. The presence of interfacial charges is a common prerequisite for
the formation of stable liposomes from mixtures of single-chain amphiphile and sterol because it favors lipid mixing and ensures the proper hydration of the self-assembly interface [25]. Nevertheless, it has been shown that all anionic lipids do not have the same impact on liposomes clearance: [10,59] some anionic phospholipid, including phosphatidylglycerol, phosphatidylinositol, and synthetic anionic acylated phosphatidylethanolamines, actually improve circulation lifetime in blood. Therefore additional investigations may identify more suitable chemical compositions of liposomes made of single-chain amphiphile and sterol (by incorporating, for example, anionic cholesterol sulfate – such as in Ref. [60]) in order to create new liposomes with extended circulation time in the blood while maintaining the reduced permeability associated with its high sterol content.

5. Conclusions

The present study identifies several characteristics of novel non-pherolipid liposomes made of PA/Chol/PEG-Chol mixtures. It is shown that up to 20 mol% of PEG-Chol can be introduced in non-phospholipid liposomes made of PA/Chol/PEG-Chol mixtures. The pharmaco-kinetics investigation of the blood circulation, a phenomenon likely associated with the bilayer core, these nanovectors are cleared relatively rapidly from the blood, a phenomenon likely associated with the presence of negatively charged unprotonated PA. The relationships between different properties of these self-assemblies with uncommon chemical composition are useful in orienting the development of superior nanovectors.
